AFOS-ERA VERIFICATION OF GUIDANCE AND  
LOCAL AVIATION/PUBLIC WEATHER FORECASTS--NO. 10  
(APRIL 1988-SEPTEMBER 1988)

Valery J. Dagostaro, Gary M. Carter, and J. Paul Dallavalle

1. INTRODUCTION

This is the tenth in the series of Techniques Development Laboratory (TDL) office notes which compare the performance of TDL's automated guidance with National Weather Service (NWS) local forecasts made at Weather Service Forecast Offices (WSFO's). Verification statistics are presented for the warm season months of April 1988 through September 1988 for probability of precipitation (POP), surface wind, cloud amount, ceiling height, visibility, and maximum/minimum (max/min) temperature. Verification summaries are provided for both forecast cycles, 0000 and 1200 UTC. The scores are those recommended in the NWS National Verification Plan (National Weather Service, 1982).

The local PoP and max/min forecasts used for verification were official public weather forecasts obtained from the Coded City Forecast (FPUS4) bulletin. The local forecasts for the aviation weather elements were obtained from the NWS official terminal forecasts (FT's). In contrast, the local cloud amount and 42-h significant wind forecasts were manually entered by the forecasters at the WSFO's. These subjective forecasts may or may not be based on the objective guidance. Also, surface observations as late as 2 hours before the first valid forecast time may have been used in preparation of the local forecasts.

The automated guidance was based on forecast equations developed by application of the Model Output Statistics (MOS) technique (Glahn and Lowry, 1972). In particular, these prediction equations were derived by using archived surface observations and forecast fields from the Limited-area Fine Mesh (LFM) Model (Gerrity, 1977; Newell and Deaven, 1981). The surface observations used as predictors in these equations were taken at least 9 hours before the first verification valid time.

Due to a change in the issuance time of the FT's in December 1986, the projections of the local and guidance forecasts for the aviation weather elements (ceiling height, visibility, and wind speed and direction) no longer match. Moreover, the observations saved locally now correspond only to the valid time of the local forecasts. The issuance time of the local forecasts is based on local time rather than the forecast cycle. Although the actual time varies with time zone and changes from standard to daylight time, for simplicity, we will refer to the FT issuance times as if they occur at the same time for all stations. We verified the local forecasts associated with the FT issuance times of approximately 0900 and 1800 UTC. Persistence forecasts corresponding to the local forecasts are also now based on the local time. Since the valid time of the automated guidance has not changed, it is no longer possible to perform a comparative verification for the aviation weather elements.

For the aviation elements, the local forecasts, along with the corresponding persistence and verifying observations, were collected locally at the WSFO's, transmitted via the Automation of Field Operations and Services (AFOS) system to the National Meteorological Center (NMC), and archived centrally by TDL.

The automated guidance for these elements was also collected locally and transmitted to NMC. The persistence and verifying observations corresponding to the guidance were taken from hourly reports archived centrally by TDL. For the remaining weather elements, including the 42-h significant wind, all of the forecasts (both local and guidance) and the verifying observations were collected locally at the WSFO's and transmitted to NMC. The local collection system is described by Ruth and Alex (1987). The national AFOS-era verification data processing system is described in detail by Dagostaro (1985), while guidelines for the public/aviation forecast verification program are given in National Weather Service (1983).

As noted in the following sections, implementation of the AFOS-era verification system introduced significant changes from past verifications in regard to the characteristics of the local forecasts and the verifying observations. For example, the local and guidance max/min temperature forecasts are verified by using max/min temperatures observed during approximately 12-h periods instead of 24-h (calendar day) periods. Also, the cloud amount observations are given in terms of total sky cover rather than opaque sky cover. Hence, we do not think it is meaningful to compare results for the 1988 warm season with statistics based on the pre-AFOS verification system (e.g., Maglaras et al., 1984).

In addition, due to the change in the issuance time of the FT's, direct comparison of the local statistics with those for the guidance is no longer possible for the aviation weather elements. Direct comparison of results for the local aviation elements for the 1988 warm season with previous warm seasons is also no longer possible.

## 2. PROBABILITY OF PRECIPITATION

MOS PoP forecasts were produced by the warm season prediction equations described in Technical Procedures Bulletin No. 299 (National Weather Service, 1981a). This guidance was available for the first, second, and third periods, which correspond to 12-24, 24-36, and 36-48 hours, respectively, after 0000 and 1200 UTC. The predictors for the equation development were forecast variables from the LFM model and weather elements observed at the forecast site at 0300 or 1500 UTC. However, in day-to-day operations, surface observations at 0200 or 1400 UTC (or even 0100 or 1300 UTC) were used as input to the prediction equations. The LFM model schedule makes this necessary, and the guidance is available earlier than if the 0300 and 1500 UTC observations were used.

The forecasts were verified by computing Brier scores (Brier, 1950) for 93 of the 94 stations listed in Table 2.1. Note that we used the standard NWS Brier score for PoP which is one-half the original score defined by Brier. Brier scores will vary from one station to the next and from one year to the next because of changes in the relative frequency of precipitation. Therefore, we also computed the percent improvement over climate, that is, the percent improvement of Brier scores obtained from the local or guidance forecasts over analogous Brier scores produced by climatic forecasts. Climatic forecasts are defined as relative frequencies of precipitation by month and by station determined from a 15-yr sample (Jorgensen, 1967). Because local forecasters are encouraged to depart from the guidance if they think it is incorrect, the Brier score was also computed when the local forecasters deviated from the guidance by at least 20%.

Tables 2.2 and 2.7 present the 1988 warm season results for all 93 stations combined, for the 0000 and 1200 UTC cycle forecasts, respectively. Tables 2.3-2.6 and Tables 2.8-2.11 show scores for the NWS Eastern, Southern, Central, and Western Regions, for the 0000 and 1200 UTC cycles, respectively.

### 3. SURFACE WIND

The objective surface wind forecasts were generated by the warm season, LFM-based equations described in Technical Procedures Bulletin No. 347 (National Weather Service, 1984). Prior to the 1984 warm season, the surface wind prediction equations were rederived to account for the latest available data from the LFM model. The objective surface wind forecast is defined in the same way as the observed wind, namely, the 1-min average wind direction and speed for a specific time. All objective forecasts of wind speed were adjusted by an "inflation" technique (Klein et al., 1959) involving the multiple correlation coefficient and the mean value of wind speed for each particular station and forecast valid time.

We verified both the local and guidance forecasts for three projections; however, due to the change in issuance time of the FT's, the projections no longer match. The guidance forecasts are valid at 12, 18, and 24 hours after both 0000 and 1200 UTC, while the local forecasts correspond to approximately 3-, 9-, and 15-h projections from the FT issuance times of approximately 0900 and 1800 UTC.

Although the MOS and local forecasts were verified separately, we used the same method of verification as in previous seasons. First, for those cases in which the wind speed forecasts were  $\geq 10$  kt, the mean absolute error and the mean algebraic error (forecast minus observed wind speed) of the forecasts were computed. Cases where the observed wind was calm were then eliminated from this sample and the MAE of direction was computed. Second, for all cases where the forecasts were available, the skill score<sup>1</sup>, percent correct, bias by category<sup>2</sup>, and threat score<sup>3</sup> were computed from contingency tables of wind speed. The definitions of the categories used in the contingency tables for wind speed and direction are given in Table 3.1. The threat score used here was calculated by combining events of the upper two categories (winds  $\geq 28$  kt). In addition, for all cases in which the wind speed forecasts were at least 10 kt, the skill score for the wind direction forecasts was computed from contingency tables. The 92 stations used in the verification are listed in Table 2.1.

For the guidance forecasts, the results for all 92 stations combined for the 0000 and 1200 UTC cycles are presented in Tables 3.2 and 3.7, respectively.

---

<sup>1</sup>The skill score used throughout this report is the Heidke skill score (Panofsky and Brier, 1965).

<sup>2</sup>In the discussion of surface wind, cloud amount, ceiling height, and visibility, bias by category refers to the number of forecasts of a particular category (event) divided by the number of observations of that category. A value of 1.0 denotes unbiased forecasts for a particular category.

<sup>3</sup>Threat score =  $H/(F+O-H)$ , where H is the number of correct forecasts of a category, and F and O are the number of forecasts and observations of that category, respectively.

Tables 3.3-3.6 and 3.8-3.11 show guidance scores for the NWS Eastern, Southern, Central, and Western Regions for 0000 and 1200 UTC, respectively. For the local forecasts, Table 3.12 (3.17) shows the results for all 91 (92) stations combined for the FT issuance time of approximately 0900 (1800) UTC. Local forecast results for the NWS Eastern, Southern, Central, and Western Regions are presented in Tables 3.13-3.16 and 3.18-3.21, respectively, for the two issuance times. Although 42-h forecasts of winds  $\geq$  23 knots were also collected as part of the AFOS-era verification system, the sample was insufficient to provide a meaningful comparative verification.

#### 4. CLOUD AMOUNT

During the 1988 warm season, the objective cloud amount forecasts were produced by the prediction equations described in Technical Procedures Bulletin No. 378 (National Weather Service, 1988). Prior to the 1988 warm season, the cloud amount prediction equations were rederived on a larger, more recent data sample from the LFM model. These regionalized equations used LFM model output and 0000 (1200) UTC surface observations to produce probability forecasts of the four categories of cloud amount shown in Table 4.1. We converted the probability estimates to "best category" forecasts by an algorithm that produced good bias characteristics (bias of approximately 1.0 for each category) on the developmental sample. The algorithm used to obtain the best category is described in Technical Procedures Bulletin No. 378.

We compared the local forecasts with a matched sample of guidance forecasts for the 94 stations listed in Table 2.1 for the 12-, 18-, and 24-h projections from 0000 and 1200 UTC. Four-category (clear, scattered, broken, and overcast), forecast-observed contingency tables were prepared from the local and objective categorical predictions. Using these tables, we computed the percent correct, skill score, and bias by category. Prior to the 1984 warm season, opaque sky cover amounts from surface observations were used in determining the observed categories. However, the hourly surface reports from which the verifying observations are now taken do not record total opaque sky cover as part of the observation; hence, thin clouds are also included. For example, a report of overcast with eight tenths opaque and two tenths thin, which previously was put into the broken category, now is categorized as overcast. The result of this change is to decrease (increase) the number of observations of the broken (overcast) category compared to previous verifications. At the same time, the number of observations of clear (scattered) has increased (decreased) because reports of thin scattered, thin broken, and thin overcast clouds are all categorized as clear. These changes have greatly affected the overall bias by category statistics for both the guidance and local forecasts.

The results for all stations combined are shown in Tables 4.2 and 4.7 for the 0000 and 1200 UTC cycle forecasts, respectively. Tables 4.3-4.6 and Tables 4.8-4.11 show scores for the NWS Eastern, Southern, Central, and Western Regions, for the 0000 and 1200 UTC cycles, respectively.

#### 5. CEILING AND VISIBILITY

During the 1988 warm season, the ceiling and visibility guidance was produced by the prediction equations described in Technical Procedures Bulletin No. 303 (National Weather Service, 1981b). Operationally, the guidance was based

primarily on LFM model output and either 0100 or 0200 (1300 or 1400) UTC surface observations.

Verification scores were computed separately for the local and guidance forecasts. A comparative verification of local and persistence forecasts was performed for 91 (92) of the 94 stations listed in Table 2.1 for the FT issuance time of approximately 0900 (1800) UTC. The local forecasts and verifying observations correspond to approximately 3-, 6-, 9-, and 15-h projections from the beginning of the scheduled FT valid period. Persistence is also based on the local time, and the projections are from the beginning of the scheduled FT valid period.

A comparative verification of guidance and persistence forecasts was performed for the same 91 (92) stations for the 0000 (1200) UTC cycle. Here, persistence for the 0000 (1200) UTC forecast cycle was based on an observation taken at the subsequent 0900 (2100) UTC. The objective and persistence forecasts were verified for 12-, 18-, and 24-h projections from both cycles. Note that the persistence forecasts for the 12-, 18-, and 24-h projections are actually 3-, 9-, and 15-h forecasts, respectively, from the latest available surface observation.

We constructed forecast-observed contingency tables for the four categories of ceiling and visibility given in Table 5.1. These categories were used for computing several different scores: bias by category, percent correct, skill score, and log score.<sup>4</sup> Table 5.2 (5.3) shows the MOS ceiling height verification results for all 91 (92) stations combined for the 0000 (1200) UTC cycle. Table 5.4 (5.5) presents the local ceiling height scores for the same 91 (92) stations except for the FT issuance time of approximately 0900 (1800) UTC. Visibility scores are given for all stations combined for the MOS forecasts in Tables 5.6 and 5.7 for the 0000 and 1200 UTC cycles, respectively. Similarly, results for the local visibility forecasts are given in Tables 5.8 and 5.9 for the FT issuance times of approximately 0900 and 1800 UTC, respectively.

## 6. MAXIMUM/MINIMUM TEMPERATURE

Throughout the 1988 warm season, the max/min temperature guidance was generated by the prediction equations described in Technical Procedures Bulletin No. 356 (National Weather Service, 1985). These equations forecast daytime max and nighttime min temperatures. During the warm season, daytime is defined as 8 a.m. to 7 p.m. Local Standard Time (LST), while nighttime extends from 7 p.m. to 8 a.m. LST. The guidance equations were developed by stratifying archived LFM model forecasts, station observations, and the first two harmonics of the day of the year into seasons of 3-mo duration (Erickson and Dallavalle, 1986). The spring season is defined as March-May; the summer, as June-August; and the fall, as September-November. During the 0000 UTC cycle, the MOS max/min guidance is valid for periods corresponding to today's max, tonight's min, tomorrow's max, and tomorrow night's min. Similarly, for the 1200 UTC forecast cycle, guidance is available for tonight's min, tomorrow's max, tomorrow night's min, and the day after tomorrow's max. Station observations at 0000 UTC

<sup>4</sup>The log score is proportional to the absolute value of  $\log_{10} f_i - \log_{10} o_i$ , where  $f_i$  is the forecast category for each case and  $o_i$  is the observed category for each case. The result is averaged over all cases and scaled by multiplying by 50.

(1200 UTC) are used as possible predictors only in the first period forecast of today's max (tonight's min). The valid periods of the guidance closely approximate those of the local forecaster who makes predictions of today's high, tonight's low, and so forth.

In this publication, we present results for both guidance and local forecasts that were verified by using observations approximating the daytime high or nighttime low. In the local AFOS-era verification software (Ruth and Alex, 1987), daytime is defined as 7 a.m. to 7 p.m. LST and nighttime as 7 p.m. to 8 a.m. LST. The local program scans the synoptic and hourly reports to determine if the max/min observation adequately represents the daytime or nighttime period. If this observation is satisfactory, it is kept. If, however, the reported value is not representative of the day or night period, then an algorithm is used to deduce the appropriate value from available synoptic and hourly temperature observations. The local forecaster is also provided the option of replacing the estimated observation with the exact nighttime low or daytime high. It's important to note, then, that the verifying observations correspond reasonably well to the local and guidance forecast periods.

We verified the local and MOS max/min temperature forecasts for both the 0000 and 1200 UTC cycles. The mean algebraic error (forecast minus observed temperature), mean absolute error, percent of absolute errors  $>10^{\circ}\text{F}$ , probability of detection<sup>5</sup> of min temperatures  $\leq 32^{\circ}\text{F}$ , false alarm ratio<sup>6</sup> for min temperatures  $\leq 32^{\circ}\text{F}$ , and percent improvement over climate<sup>7</sup> were computed for 93 stations in the conterminous United States (see Table 2.1). At 0000 (1200) UTC, the local max temperature forecasts are valid for daytime periods ending approximately 24 (36) and 48 (60) hours after 0000 (1200) UTC. Similarly, at 0000 (1200) UTC, the local min temperature forecasts are valid for nighttime periods ending about 36 (24) and 60 (48) hours after 0000 (1200) UTC.

For all stations combined, the results for 0000 and 1200 UTC are shown in Tables 6.1 and 6.6, respectively. Similarly, Tables 6.2-6.5 give the 0000 UTC cycle verification scores for the Eastern, Southern, Central, and Western Regions, respectively. Tables 6.7-6.10 show analogous scores by NWS region for the 1200 UTC cycle.

---

<sup>5</sup>Here, the probability of detection is defined to be the fraction of time the min temperature was correctly forecast to be  $\leq 32^{\circ}\text{F}$  when the previous day's min was  $\geq 40^{\circ}\text{F}$ .

<sup>6</sup>Here, the false alarm ratio is defined to be the fraction of forecasts of  $\leq 32^{\circ}\text{F}$  that failed to verify when the previous day's min was  $\geq 40^{\circ}\text{F}$ .

<sup>7</sup>The percent improvement over climate is the percent improvement of mean square errors obtained from the local or guidance forecasts over analogous mean square errors produced by climatic forecasts. The climatic values used here are the National Climatic Data Center's normal max or min temperatures for each station determined from a 30-yr sample.

## 7. SUMMARY

Highlights of the 1988 warm season verification results, summarized by general type of weather element, are:

- o Probability of Precipitation - The PoP verification involved 93 stations and forecast projections of 12-24, 24-36, and 36-48 hours from 0000 and 1200 UTC. The NWS Brier scores for all stations and both forecast cycles combined show that the local forecasts were 2.9% better than the guidance for the first period, 1.3% better for the second period, and less than 1% better for the third period. Depending on the projection and cycle, the local forecasters deviated by 20% or more from the guidance about 10% of the time. In those cases, the NWS Brier scores for all stations and both forecast cycles combined show that the local forecasters were 7.0% better than the guidance for the first period, 2.4% better for the second period, and 1.2% better for the third period. The Brier scores and percent improvement over climate scores for all three periods and both forecast cycles combined indicate that the local and guidance forecasts were better than those for the previous warm season (Dagostaro et al., 1988).
- o Surface Wind - Statistics were computed for local and guidance forecasts of surface wind speed and direction. Local forecasts for 91 (92) stations for projections of around 3, 9, and 15 hours from the FT issuance times of approximately 0900 and 1800 UTC were verified. Local forecasts based on the new FT issuance time were first verified for an entire warm season in 1988; thus, a comparison of results with those of the previous warm season was not possible.

Guidance forecasts for the same 92 stations for projections of 12, 18, and 24 hours from 0000 and 1200 UTC were verified. The mean absolute error and skill score for all stations, projections, and both forecast cycles combined show that the MOS wind direction forecasts were generally better than for the previous warm season. The bias by category for all stations, projections, and both cycles show that the wind speed forecasts were generally better than those for the previous warm season for wind speeds  $>13$  kt; however, in terms of percent correct, the forecasts for all speeds ( $\leq 12$  kt) were worse than last year's results. The mean absolute error, mean algebraic error, skill score, and threat score varied from projection to projection and cycle to cycle, indicating no clear trends.

- o Cloud Amount - The verification for cloud amount involved 94 stations and forecasts for projections of 12, 18, and 24 hours from 0000 and 1200 UTC. The skill scores and percents correct for all stations combined indicate both the 0000 and 1200 UTC cycle local forecasts were better than the corresponding guidance for the 12-h projection, while the guidance was better than the local forecasts for the 18- and 24-h projections. In terms of bias by category (clear, scattered, broken, and overcast), the local forecasts were usually better than the guidance for predictions of scattered, but were worse than the guidance for predictions of clear and broken.

In terms of skill score and percent correct, the guidance forecasts were generally better than those for the previous warm season. For the local forecasts, results varied from projection to projection and cycle to cycle, indicating no clear trends.

- o Ceiling and Visibility - Both the local and guidance forecasts were verified against their corresponding persistence forecasts. For the local forecasts, a comparative verification was performed for 91 (92) stations for projections of around 3, 6, 9, and 15 hours from the FT issuance times of approximately 0900 and 1800 UTC. For the guidance, the verification involved the comparison of MOS forecasts and persistence for the same 91 (92) stations for projections of 12, 18, and 24 hours from 0000 (1200) UTC. These are actually 3-, 9-, and 15-h forecasts from the latest available surface observations for persistence.

For both forecast cycles, the log scores, percents correct, and skill scores show that persistence was more accurate than the guidance forecasts for the 12-h projection for both ceiling and visibility. The guidance was always better than persistence for the 18- and 24-h projections from 0000 UTC. For these same two projections from 1200 UTC, the guidance was usually better than persistence in terms of skill score, but worse in terms of log score and percent correct. The bias by category scores varied greatly from projection to projection and cycle to cycle. In terms of log score and percent correct, the guidance forecasts for ceiling and visibility were better than those for the previous warm season; however, in terms of skill score, the guidance was usually worse than last year's forecasts.

For the local forecasts of ceiling and visibility, the log score, percent correct, and skill score indicate that the forecasts were usually worse than persistence for the 3-h projection, but were usually better for the 9- and 15-h projections. The bias by category results varied, except that the lowest two categories were underforecast by the local forecasters for all projections. Local forecasts based on the new FT issuance time were first verified for an entire warm season in 1988; thus, a comparison of results with those of the previous warm season was not possible.

- o Maximum/Minimum Temperature - Objective and local forecasts were verified for 93 stations for both the 0000 and 1200 UTC cycles. At 0000 (1200) UTC, the local maximum temperature forecasts were valid for daytime periods ending approximately 24 (36) and 48 (60) hours after 0000 or 1200 UTC, while the minimum temperature forecasts were valid for nighttime periods ending approximately 36 (24) and 60 (48) hours after initial model time. The valid periods of the guidance closely approximate those of the local forecasts. As verifying observations, max or min temperatures for daytime or nighttime intervals were used.

For all stations and projections combined, we found the mean absolute errors of the local max and min temperature forecasts were  $0.3^{\circ}\text{F}$  and  $0.1^{\circ}\text{F}$ , respectively, more accurate than the MOS guidance. For all stations combined, the local forecasters were almost always able to improve over the MOS guidance, both in terms of mean absolute error and the percentage of errors  $>10^{\circ}\text{F}$ . For all stations and projections combined, both the local and guidance verification results were worse than for the previous warm season in terms of mean algebraic error, mean absolute error, and percentage of errors  $>10^{\circ}\text{F}$ ; however, the mean absolute

error for the 1987 warm season was the lowest recorded for the warm season since 1966 (Carter and Polger, 1986).

Table 2.1. Ninety-four stations used for comparative verification of MOS guidance and local probability of precipitation, surface wind, cloud amount, ceiling height, visibility, and max/min temperature forecasts. Please note that LAX was not included in the PoP and max/min temperature verifications, and LBB and ELP were not included in the surface wind, ceiling height, and visibility verifications. TCC was not available during the 0000 GMT cycle for the local surface wind, ceiling height, and visibility verifications.
